Abstract. Triangle counting is an important problem in graph mining. Clustering coefficients of vertices and the transitivity ratio of the graph are two metrics often used in complex network analysis. Furthermore, triangles have been used successfully in several real-world applications. However, exact triangle counting is an expensive computation. In this paper we present the analysis of a practical sampling algorithm for counting triangles in graphs. Our analysis yields optimal values for the sampling rate, thus resulting in tremendous speedups ranging from 2800x to 70000x when applied to real-world networks. At the same time the accuracy of the estimation is excellent.

Our contributions include experimentation on graphs with several millions of nodes and edges, where we show how practical our proposed method is. Finally, our algorithm's implementation is a part of the PEGASUS library ³ a Peta-Graph Mining library implemented in Hadoop, the open source version of Mapreduce.

1 Introduction

Graphs are ubiquitous: the Internet, the World Wide Web (WWW), social networks, protein interaction networks and many other complicated structures are modelled as graphs. The problem of counting subgraphs is one of the typical graph mining tasks that has attracted a lot of attention ([13], [14], [15]) due to the wealth of applications related to it. Indicatively we report the following: a) Frequent small subgraphs are considered as a “basis”, i.e., building blocks, for constructing classes of real-world networks [21],[3]. b) In complex network analysis, computation of the transitivity ratio and the clustering coefficients requires computing the number of triangles in the graph [23]. c) Community detection is a significant problem in many different scientific fields, e.g., parallel computation, computer vision([26]), linear algebra([17]), including graph mining [20,28,17].

³ Code and datasets are available at <http://www.cs.cmu.edu/~ctsourak/>.

Subgraph patterns such as bipartite cores or nearly “bipartite cliques”, are used to detect emerging communities in the WebGraph [18] d) Fraudsters in online auction networks reportedly [25] seem to form specific patterns of connections, e.g., dense bipartite subgraphs.

The most basic, non-trivial subgraph, is the triangle. More formally, given a simple, undirected graph $G(V, E)$, a triangle is a three node fully connected subgraph. Many social networks have abundant triangles, since typically friends of friends tend to become friends themselves [36]. This phenomenon is observed in other types of networks as well (biological, online networks etc.) and is one of the main factors that gave rise to the definitions of the transitivity ratio and the clustering coefficients of a graph [23]. Triangles have also been used in several applications. Namely, they have been used by Eckmann and Moses in [10] to uncover the hidden thematic structure of the web and as a feature to assist the classification of web activity as spamming or not, by Becchetti, Boldi, Castillo and Gionis in [5].

In this paper we analyze a recent sampling algorithm for counting triangles which appeared in [34]. In [34] only constant values of the sparsification parameter, i.e., sampling rate, were tested. A natural question to ask is how small can the sample be? If p could be for example $O(\frac{1}{\sqrt{n}})$ while having guarantees that the estimate is concentrated around the true value of the number of triangles in G , then the speedup would grow linearly with the number of nodes using an algorithm as the node iterator [34], giving tremendous speedups. Our main contribution is the rigorous analysis of Doulion [34], which yields optimal values for the sparsification parameter p . We run our proposed method on large networks, showing speedups that reach the scale of about 70000 faster performance with respect to the triangle counting task.

The paper is organized as follows: Section 2 presents briefly the existing work and the theoretical background, Section 3 presents our proposed optimal sampling method and Section 4 presents the experimental results on several large graphs. Section 5 presents two theoretical ramifications and in Section 6 we conclude.

2 Preliminaries

In this section, we briefly present the existing work on the triangle counting problem and the necessary theoretical background of our analysis. Table 1 lists the symbols used in this paper.

2.1 Existing work

There exist two general categories of triangle counting algorithms, the exact and the approximating counting algorithms.

Exact Counting The fastest exact counting methods use matrix-matrix multiplication and therefore the overall time complexity is $O(n^{2.371})$, which is the

Symbol	Definition
G	a graph
n	number of nodes in G
m	number of edges in G
t	number of triangles in G
$\Delta(e)$	# triangles that edge e participates
Δ	$\max \Delta(e)$
p	sparsification parameter
p^*	a p value which gives concentration
p_I^*	ideal p value, $p_I^* = \min(p^*)$
T	random variable, estimate of t

Table 1. Table of symbols

state of the art complexity for matrix multiplication [8]. The space complexity is $O(n^2)$. This category of algorithms are not used in practice due to the high memory requirements. Even for medium sized networks, matrix-multiplication based algorithms are not applicable.

Listing algorithms, even if they solve a more general problem than the counting one, are preferred in practice for large graphs, due to the smaller memory requirements. Simple representative algorithms are the node- and the edge-iterator algorithms. In the former, at each iteration the algorithm considers the neighborhood of each node and counts the number of edges among the neighbors, whereas the latter at each iteration considers an edge and counts the common neighbors of the endpoints. Both have the same asymptotic complexity $O(mn)$, which in dense graphs results in $O(n^3)$ time, the complexity of the naive counting algorithm. Practical improvements over this family of algorithms have been achieved using various techniques, such as hashing to check if two nodes are neighborhood or not in constant time or sorting by the degree to avoid unnecessary comparisons of neighborhoods of nodes ([19,29]).

In planar graphs, Itai and Rodeh [11] and also Papadimitriou and Yannakakis [24] showed that triangles can be found in $O(n)$ time. Itai and Rodeh in [11] proposed an algorithm to find a triangle in any graph in $O(m^{\frac{3}{2}})$, which can be extended to list the triangles in the graph with the same time complexity. Their algorithm iteratively computes a spanning tree of the graph until there are no edges left, checks for each edge (u, w) that does not belong to the spanning tree whether it belongs to a triangle w.r.t the spanning tree and then removes the edges of the spanning tree.

The state of the art counting algorithm is due to Alon, Yuster and Zwick in [2] and runs in $O(m^{\frac{2\omega}{\omega+1}})$, where $\omega=2.371$, the fast matrix multiplication exponent ([8]). Thus, the Alon et al. algorithm currently runs in $O(m^{1.41})$ time.

Approximate Counting In many applications such as the ones mentioned in Section 1 the exact number of triangles is not crucial. Thus approximating algorithms that are faster and output a high quality estimate are desirable. Most of the approximate triangle counting algorithms have been developed in the streaming setting. In this scenario, the graph is represented as a stream. Two main representations of a graph as a stream are the edge stream and the incidence stream. In the former, edges are arriving one at a time. In the latter scenario all edges incident to the same vertex appear successively in the stream. The ordering of the vertices is assumed to be arbitrary. A streaming algorithm produces a relative ϵ approximation of the number of triangles with high probability, making a constant number of passes over the stream. However, sampling algorithms developed in the streaming literature can be applied in the setting where the graph fits in the memory as well.

Monte Carlo sampling techniques have been proposed to give a fast estimate of the number of triangles. According to such an approach, a.k.a. naive sampling, we choose three nodes at random repetitively and check if they form a triangle or not. If one makes

$$r = \log\left(\frac{1}{\delta}\right) \frac{1}{\epsilon^2} \left(1 + \frac{T_0 + T_1 + T_2}{T_3}\right)$$

independent trials where $T_i = \#\text{triples with } i \text{ edges}$ and outputs as the estimate of triangles the random variable $T'_3 = \binom{n}{3} \frac{\sum_{i=1}^r X_i}{r}$ then

$$(1 - \epsilon)T_3 < T'_3 < (1 + \epsilon)T_3$$

with probability at least $1 - \delta$. For graphs that have $T_3 = o(n^2)$ triangles this approach is not suitable. This is the typical case, when dealing with real-world networks. This sampling approach is presented in [30].

Yosseff, Kumar and Sivakumar in their seminal paper [4] reduce the problem of triangle counting efficiently to estimating moments for a stream of node triples. Then they use the Alon-Matias-Szegedy algorithms [1] (a.k.a. AMS algorithms) to proceed. The key is that the triangle computation reduces in estimating the zero-th, first and second frequency moments, which can be done efficiently. Again, as in the naive sampling, the denser the graph the better the approximation. The AMS algorithms are also used by [12], where simple sampling techniques are used, such as choose an edge from the stream at random and check how many common neighbors its two endpoints share considering the subsequent edges in the stream. In the same lines, Buriol et al. in [7] proposed two space-bounded sampling algorithms to estimate the number of triangles. Again, the underlying sampling procedures are simple. E.g., for the case of the edge stream representation, they sample randomly an edge and a node in the stream and check if they form a triangle. Their algorithms are the state-of-the-art algorithms to the best of our knowledge. In their three-pass algorithm, in the first pass they count the number of edges, in the second pass they sample uniformly at random an edge (i, j) and a node $k \in V - \{i, j\}$ and in the third pass they test whether the edges $(i, k), (k, j)$ are present in the stream. The number of draws

that have to be done in order to get concentration (of course these draws are done in parallel), is of the order

$$r = \log\left(\frac{1}{\delta}\right) \frac{2}{\epsilon^2} \left(3 + \frac{T_1 + 2T_2}{T_3}\right)$$

Even if the term T_0 is missing compared to the naive sampling, the graph has still to be fairly dense with respect to the number of triangles in order to get an ϵ approximation with high probability.

In the special case of “power-law” networks Tsourakakis [33] showed that the spectral counting of triangles can be efficient due to the spectrum properties of this category networks. This algorithm can be viewed as a special case of a streaming algorithm, since there exist algorithms ([27]) that perform a constant number of passes over the non-zero elements of the matrix to make a good w.r.t the SVD, low rank approximation of a matrix. In [5] the semi-streaming model for counting triangles is introduced. Becchetti et. al. observed that since counting triangles reduces to computing the intersection of two sets, namely the induced neighborhoods of two adjacent nodes, ideas from the locality sensitivity hashing [6] are applicable to the problem of counting triangles. They relax the constraint of a constant number of passes over the edges, by allowing $\log n$ passes.

DOULION Doulion, a recent algorithm which appeared in [34] proposed a new sampling procedure. The algorithm tosses a coin independently for each edge with probability p to keep the edge and probability $q = 1 - p$ to throw it away. In case the edge “survives”, it gets reweighted with weight equal to $\frac{1}{p}$. Then, any triangle counting algorithm, such as the node- or edge- iterator, is used to count the number of triangles t' in G' . The estimate of the algorithm is the random variable $T = \frac{t'}{p^3}$. The following facts -among others- were shown in [34]:

- The estimator T is unbiased, i.e., $\mathbb{E}[T] = t$.
- The expected speedup when a simple exact counting algorithm as the node iterator is used, is $1/p^2$.

The authors however did not answer a critical question: how small can p be? In [34] constant factor speedups were obtained leaving the question as a topic of future research.

2.2 Concentration of boolean Polynomials

A common task in combinatorics is to show that if Y is a polynomial of independent boolean random variables then Y is concentrated around its expected value. In the following we state the necessary definitions and the main concentration result which we will use in our method.

Let $Y = Y(t_1, \dots, t_m)$ be a polynomial of m real variables. The following definitions are from [32]. Y is totally positive if all of its coefficients are non-negative variables, regular if all of its coefficients are between zero and one, simplified if all of its monomials are square free and homogeneous if all of its

monomials have the same degree. Given any multi-index $\alpha = (\alpha_1, \dots, \alpha_m) \in \mathbb{Z}_+^m$, define the partial derivative $\partial^\alpha Y = (\frac{\partial}{\partial t_1})^{\alpha_1} \dots (\frac{\partial}{\partial t_m})^{\alpha_m} Y(t_1, \dots, t_m)$ and denote by $|\alpha| = \alpha_1 + \dots + \alpha_m$ the order of α . For any order $d \geq 0$, define $\mathbb{E}_d(Y) = \max_{\alpha: |\alpha|=d} \mathbb{E}(\partial^\alpha Y)$ and $\mathbb{E}_{\geq d}(Y) = \max_{d' \geq d} \mathbb{E}_{d'}(Y)$.

Typically, when Y is smooth then it is strongly concentrated. By smoothness one usually means a small Lipschitz coefficient. In other words, when one changes the value of one variable t_j , the value Y changes no more than a constant. However, as stated in [35] this is restrictive in many cases. Thus one can demand “average smoothness” as defined in [35]. For the purposes of this work, consider a random variable $Y = Y(t_1, \dots, t_m)$ which is a positive polynomial of m boolean variables $[t_i]_{i=1..m}$ which are independent. Observe that a boolean polynomial is always regular and simplified.

Now, we refer to the main theorem of Kim and Vu of [16, §1.2] as phrased in Theorem 1.1 of [35] or as Theorem 1.36 of [32].

Theorem 1. *There is a constant c_k depending on k such that the following holds. Let $Y(t_1, \dots, t_m)$ be a totally positive polynomial of degree k , where t_i can have arbitrary distribution on the interval $[0, 1]$. Assume that:*

$$\mathbb{E}[Y] \geq \mathbb{E}_{\geq 1}(Y) \quad (1)$$

Then for any $\lambda \geq 1$:

$$\Pr \left[|Y - \mathbb{E}[Y]| \geq c_k \lambda^k (\mathbb{E}[Y] \mathbb{E}_{\geq 1}(Y))^{1/2} \right] \leq e^{-\lambda + (k-1) \log m}. \quad (2)$$

3 Proposed Method

3.1 Analysis

Now, we analyze a simple sparsification procedure which first appeared in [34]: toss a coin for each edge with probability p to keep the edge and probability $q = 1 - p$ to throw it away. In case the edge “survives”, we reweigh it with weight equal to $\frac{1}{p}$. Observe that since the initial graph was unweighted, all edges in the resulting sparsified graph G' have weight equal to $\frac{1}{p}$, thus we just have to store a single number. Now, we count weighted triangles in the sparsified graph G' . Our main result is the following theorem.

Theorem 2. *Suppose G is an undirected graph with n vertices, m edges and t triangles. Let also Δ denote the size of the largest collection of triangles with a common edge. Let G' be the random graph that arises from G if we keep every edge with probability p and write T for the number of triangles of G' . Suppose that $\gamma > 0$ is a constant and*

$$\frac{pt}{\Delta} \geq \log^{6+\gamma} n, \quad \text{if } p^2 \Delta \geq 1, \quad (3)$$

and

$$p^3 t \geq \log^{6+\gamma} n, \quad \text{if } p^2 \Delta < 1. \quad (4)$$

for $n \geq n_0$ sufficiently large. Then

$$\mathbf{Pr} [|T - \mathbb{E}[T]| \geq \epsilon \mathbb{E}[T]] \leq n^{-K}$$

for any constants $K, \epsilon > 0$ and all large enough n (depending on K, ϵ and n_0).

Proof. Write $X_e = 1$ or 0 depending on whether the edge e of graph G survives in G' . Then $T = \sum_{\Delta(e,f,g)} X_e X_f X_g$ where $\Delta(e, f, g) = \mathbf{1}$ (edges e, f, g form a triangle). Clearly $\mathbb{E}[T] = p^3 t$.

Refer to Theorem 1. We use T in place of Y , $k = 3$.

We have

$$\mathbb{E} \left[\frac{\partial T}{\partial X_e} \right] = \sum_{\Delta(e,f,g)} \mathbb{E}[X_f X_g] = p^2 |\Delta(e)|,$$

where $\Delta(e) =$ to how many triangles edge e participates. We first estimate the quantities $\mathbb{E}_j(T)$, $j = 0, 1, 2, 3$, defined before Theorem 1. We get

$$\mathbb{E}_1(T) = p^2 \Delta \tag{5}$$

where $\Delta = \max_e |\Delta(e)|$.

We also have

$$\mathbb{E} \left[\frac{\partial^2 T}{\partial X_e \partial X_f} \right] = p \mathbf{1}(\exists g : \Delta(e, f, g)),$$

hence

$$\mathbb{E}_2(T) \leq p. \tag{6}$$

Obviously $\mathbb{E}_3(T) \leq 1$.

Hence

$$\mathbb{E}_{\geq 3}(T) \leq 1, \quad \mathbb{E}_{\geq 2}(T) \leq 1,$$

and

$$\mathbb{E}_{\geq 1}(T) \leq \max \{1, p^2 \Delta\}, \quad \mathbb{E}_{\geq 0}(T) \leq \max \{1, p^2 \Delta, p^3 t\}.$$

• CASE 1 ($p^2 \Delta < 1$):

We get $\mathbb{E}_{\geq 1}(T) \leq 1$, and, from (4), $\mathbb{E}_{\geq 0}(T) = p^3 t$.

• CASE 2 ($p^2 \Delta \geq 1$):

We get $\mathbb{E}_{\geq 1}(T) \leq p^2 \Delta$, and, from (3), $\mathbb{E}_{\geq 0}(T) = p^3 t$.

We get, for some constant $c_3 > 0$, from Theorem 1:

$$\mathbf{Pr} \left[|T - \mathbb{E}[T]| \geq c_3 \lambda^3 (\mathbb{E}[T] \mathbb{E}_{\geq 1}(T))^{1/2} \right] \leq e^{-\lambda + 2 \log n}. \tag{7}$$

Notice that in both cases we have $\mathbb{E}[T] \geq \mathbb{E}_{\geq 1}(T)$.

We now select λ so that the lower bound inside the probability on the left-hand side of (7) becomes $\epsilon \mathbb{E}[T]$. In Case 1 we pick

$$\lambda = \frac{\epsilon^{1/3}}{c_3^{1/3}} (p^3 t)^{1/6}$$

while in Case 2

$$\lambda = \frac{\epsilon^{1/3}}{c_3^{1/3}} \left(\frac{pt}{\Delta} \right)^{1/6}$$

to get

$$\Pr [|T - \mathbb{E}[T]| \geq \epsilon \mathbb{E}[T]] \leq \exp(-\lambda + 2 \log n) \quad (8)$$

Since $\lambda \geq (K+2) \log n$ follows from our assumptions (3) and (4) if n is sufficiently large, we get $\Pr [|T - \mathbb{E}[T]| \geq \epsilon \mathbb{E}[T]] \leq n^{-K}$, in both cases.

3.2 Remarks

This theorem states the important result that the estimator of the number of triangles is concentrated around its expected value, which is equal to the actual number of triangles t in the graph [34] under mild conditions on the triangle density of the graph. The mildness comes from condition (3): picking $p = 1$, given that our graph is not triangle-free, i.e., $\Delta \geq 1$, gives that the number of triangles t in the graph has to satisfy $t \geq \Delta \log^{6+\gamma} n$. This is a mild condition on t since $\Delta \leq n$ and thus it suffices that $t \geq n \log^{6+\gamma} n$ (after all, we can always add two dummy connected nodes that connect to every other node, as in Figure 1, even if practically -experimentally speaking- Δ is smaller than n). The critical quantity besides the number of triangles t , is Δ . Intuitively, if the sparsification procedure throws away the common edge of many triangles, the triangles in the resulting graph may differ significantly from the original.

A significant problem is the choice of p for the sparsification. The conditions (3) and (4) tell us how small we can afford to choose p , but the quantities involved, namely t and Δ , are unknown. One way around this obstacle would be to first estimate the order of magnitude of t and Δ and then choose p a little suboptimally. It may be possible to do this by running the algorithm a small number of times and deduce concentration if the results are close to each other. If they differ significantly then we sparsify less, say we double p , and so on, until we observe stability in our results. This would increase the running time by a small logarithmic factor at most. As we will describe in Section 4, in practice the doubling p idea, works well.

From the theoretical point of view, this ambiguity of how to choose p to be certain of concentration in our sparsification preprocessing does not however render our result useless. Under very general assumptions on the nature of the graph one should be able to get a decent value of p . For instance, if we know $t \geq n^{3/2+\epsilon}$ and $\Delta \sim n$, we get $p = n^{-1/2}$. This will result in a linear $O(n)$ expected speedup, as already mentioned in section 2. On the other hand, if one wishes to make no assumptions on the nature of the graph, he/she can pick a constant p , e.g., $p = c$, and obtain expected speedups of order $\frac{1}{c^2}$ as described in [34].

4 Experiments

In this section we describe first the experimental setup, and then we present the experimental results. We close the section by providing a practitioner’s guide on how to use the analyzed triangle counting algorithm through the detailed description of a specific experiment.

4.1 Experimental Setup

Datasets Table 2 describes in brief the real-world networks we used in our experiments ⁴. All graphs were first made undirected, and all self-loops were removed. The description of table 2 refers to the graphs after the preprocessing.

Algorithm We implemented the node iterator algorithm which was described in Section 2 and was also used in [34]. The code is written in JAVA and in Hadoop, the open source version of MapReduce [9].

Machines We used two machines to run our experiments. The experiments for the three smallest graphs (Wikipedia 2005/9, Flickr, Youtube) were executed in a 2GB RAM, Intel(R) Core(TM)2 Duo CPU at 2.4GHz Ubuntu Linux machine. For the three larger graphs (WB-EDU, Wikipedia 2006, Wikipedia 2005), we used the M45 supercomputer, one of the fifty most powerful supercomputers in the world. M45 has 480 hosts (each with 2 quad-core Intel Xeon 1.86 GHz, running RHEL5), with 3Tb aggregate RAM, and over 1.5 PetaByte aggregate disk capacity. The cluster is running Hadoop on Demand (HOD). The number of machines allocated by HOD was set equal to three (3), given the relative small size of the graphs (≈ 600 -700 MB). The sparsification triangle counting algorithm Doulion, i.e., sparsification and counting in the sparsified graph were executed for all datasets in the Ubuntu machine.

4.2 Experimental Results

Given that the majority of our datasets has n of order $\approx 10^6$ we begin with a sparsification value $p = 0.005$ which is $\approx 1/\sqrt{n}$. We tried even smaller values than that (e.g, 0.001, 0.0005), but there was no concentration for any of the datasets. We keep doubling the sparsification parameter until we deduce concentration and stop. In table 3, we report the results. In more detail, each row corresponds to the p^* value, that we first deduced concentration using the doubling procedure for each of the datasets we used (column 1). Ideally we would like to find p_I^* , but we will settle with a p^* value, since as already mentioned, doubling gives at most an increase by a small logarithmic factor. Observe that p^* is at most 2 times more than p_I^* and upon its identification, if one is curious about p_I^* for

⁴ Most of the datasets can be found on the web, <http://www.cise.ufl.edu/research/sparse/matrices/>. The Youtube graph was made to us available upon request, [22]

Table 2. Description of datasets

some reason, he/she can just do a simple “binary” search. The third column of table 3 described the quality of the estimator. Particularly, it contains values of the ratio $our\ estimate / \#triangles$. The next column contains the running time of the sparsification code, i.e., how much time it takes to make one pass over the data and generate a second file containing the edges of the sparsified graph. The fourth column *xfaster 1* contains the speedup of the node iterator vs. itself when applied to the original graph and to the sparsified graph, i.e., the sample. The last column, *xfaster 2*, contains the speedup of the whole procedure we suggest, i.e., the doubling procedure, counting and repeat until concentration deduction, vs. running node iterator on the original graph.

Some interesting points concerning these experimental results are the following: a) The concentration we get is strong for small values of p , which implies directly large speedups. b) The speedups typically are close to the expected ones, i.e., $\frac{1}{p^2}$ for the experiments that we conducted in whole in the small (Ubuntu) machine. For the three experiments that were conducted using Hadoop, the speedups were larger than the expected ones. This was (at least partially) expected since the necessary time for the JVM (Java Virtual Machine) to load in M45, the disk I/O and most importantly the network communication increase the running time for the node iterator algorithm when executed in parallel. However, for larger graphs that would span several Gigabytes, this speedup excession that we observed in our experiments should not show up as much. The most important point to keep besides the system details is that our theorem guarantees concentration which implies that observing almost the same estimate in the sparsified graph multiple times is equivalent to being able to make a good estimate for the true number of triangles. c) Even if the “doubling-and-checking for concentration” procedure may have to be repeated several times the sparsification algorithm is still of high practical value. This is witnessed by the last column of the table. d) The overall speedups in the last column can easily be increased if one is willing to be less conservative in the following sense: we conducted six experiments to deduct concentration. But in practice, one could conduct concen-

tration using e.g., four experiments. Typically, concentration is easy to deduce. In the Wikipedia 2005/09 experiment, the first four experiments give 354, 349, 348 and 350 triangles in the sparsified graph which upon division with 0.02^3 result in high accuracy estimates. e) Finally, when concentration is deducted, averaging the concentrated estimates, typically gives a reasonable estimator of high accuracy.

G	p^*	Mean Accuracy (6 experiments)	Sparsify (secs)	x_{faster} 1	x_{faster} 2
WB-EDU	0.005	95.8	8	70090	370.4
Wiki-2007	0.01	97.7	17	21000	332
Wiki-2006	0.02	94.9	14	4000	190.47
Wiki-2005	0.02	96.8	8.6	2812	172.1

Table 3. Experimental results. Observe how small can p be, resulting in huge savings during the triangle counting time. The “doubling-and-checking for concentration” procedure that one would employ in practice gives important savings and high accuracy at the same time. The drop-off in the total speedup is mainly due to the sparsification time.

4.3 A Practitioner’s guide

At first sight, according to theorem 2 in order to pick the optimal value for p we have to know the quantity that we are trying to compute, i.e., t (and also Δ). Even if one knows nothing about the triangle density of the graph of interest, or wishes to make no assumptions, the proposed method is still of high practical value. In this subsection our goal is to provide a practitioner’s guide. Specifically, we describe in detail how one can apply the sampling algorithm to a real world network, using our experimental experience as a guide, through an example. Specifically, we describe how one can run the sampling algorithm in practice by “zooming” in the Wikipedia 2005/9 experiment.

The Wikipedia 2005/9 graph after made undirected has $n = 1,634,989$ nodes and 18,540,603. The total number of triangles in the graph is $t = 45,542,697$. A simple computation gives that the triangle density $\frac{t}{\binom{n}{3}}$ is equal to $6.25 \cdot$

p	Ratios $\frac{T}{t}$	Sparsifi- cation (secs)	Average Speedup (<i>x_{faster}</i>)

Table 4. Wikipedia 2005/09: In this example, one deduces concentration for $p = 0.02$. The corresponding speedup (node iterator on G and on a small sample of G) averaged over the ten experiments is 2880 times. Results for p greater than 0.02 show that above that value strong concentration is achieved.

10^{-11} . This is a phenomenon that is observed with all the networks we used, i.e., very low triangle density. This should not be surprising, since “real-world networks” exhibit very skewed degree distributions. Roughly speaking, there exist many nodes with degree one, often connected to degrees of low degree, e.g., 2. Immediately those nodes, i.e. nodes of degree 1 and of degree 2 that are connected with nodes of degree one, participate in no triangles. Furthermore, many nodes are totally disconnected, having degree zero. Even if the triangle density assumption (3) of our theorem is violated, the way to run the algorithm is the same. The value of p will be necessarily bigger to have concentration (the closer we get to a linear number of triangles, the larger p gets so as to have concentration), but as Table 3 suggests, the method is of high practical value. One can start with a small sparsification value for $p = 0.01$ ⁵

For $p = 0.01$, running the sparsification code in a small machine with 2GB RAM, Intel(R) Core(TM)2 Duo CPU at 2.4GHz Ubuntu Linux machine, the sparsification takes ≈ 8 seconds and the counting (excluding the time to read the graph into the memory) procedure using the simple node iterator algorithm takes 0.35 seconds. We ran this experiment four times, to make sure that this specific value of p gives us the desired concentration. The number of triangles in the sparsified graph were found to be equal to 43, 66, 52 and 60. Thus the estimates that the algorithm makes are respectively 4.3×10^7 , 6.6×10^7 , 5.2×10^7 and 6×10^7 . As one can observe, even if the average of those estimates gives an accuracy of

⁵ As described in the previous subsection we start with even smaller value, but for brevity reasons, we begin here with 0.01 since concentration appears for $p = 0.02$.

Fig. 1. Linear number of triangles: If our biased coin decides to delete edge (1,2), then our sampling approach misses all triangles.

82.43%, the variance of those estimates is large. Thus, the value $p = 0.01$ is not to be trusted. Doubling p , i.e., $p = 0.02$, and running the code 10 times results in the following estimate of the number of triangles: 4.15×10^7 , 4.25×10^7 , 4.6375×10^7 , 4.0875×10^7 , 4.3625×10^7 , 4.3375×10^7 , 4.35×10^7 , 4.375×10^7 , 4.45×10^7 , 4.25×10^7 . The sparsification procedure takes ≈ 9 seconds and the counting procedure in average 2.46 seconds with variance equal to 0.1 second and can easily run in a machine with insufficient memory. The speedup using $p = 0.02$ due to our method is in average 2880, compared to running the node iterator in the initial graph. And as shown in the previous subsection the doubling idea still results in important speedups. If one tries slightly larger values for p , he/she would observe a strong concentration suggesting that we have a good estimate.

The above are summarized in table 4. Each row corresponds to more than one experiments for a specific value of p . The first column shows the sparsification parameter, the second column contains the ratios $\frac{T}{t}$, and there are as many of them as the number of experiments were conducted for p value in the same row, the third column contains the running time of the sparsification procedure and the last column the average speedup obtained when we run the node iterator on the whole graph and on the small sample we obtain using the sparsification procedure. In this example, one can deduce at $p = 0.02$ concentration and stop running the algorithm. As we observe, given a graph G the sparsification time is more or less the same (8-9sec), correlated positively with p , as more I/O write operations are being done (writing edges to a new file). The speedup we get averaged over the experiments we did compared to the expected one, can be approximately the (e.g., $p = 0.05$), can be larger (e.g., $p = 0.02$) and can be also smaller (e.g., $p = 0.01$).

5 Theoretical Ramifications

5.1 Linear number of triangles

One may wonder how the algorithm performs in graphs where the number of triangles is linear, i.e., $O(n)$. Consider the graph of figure 1. If the coin decides that the common edge should be removed then we lose all the triangles. Thus the sparsification step may introduce an arbitrarily high error in our estimate.

5.2 Weighted graphs

Fig. 2. Weighted case: For w sufficiently large, our sampling approach can perform badly if one of the weighted edges gets deleted.

Consider now the case of weighted graphs. The algorithm of [34] can be extended to weighted graphs: each edge gets reweighted with weight equal to the old weight times $1/p$. However, one can come up with counterexamples that show that this algorithm can perform badly on weighted graphs. Such an example where the algorithm can perform badly is shown in figure 2. If w is large enough, then the removal of one of the weighted edges will introduce a large error in the final estimate.

6 Conclusions

We present an algorithm that under mild conditions on the triangle density of the graph performs accurately, i.e., outputs a good estimate of the number of triangles, with high probability.

Our main contributions are:

- The analysis of the sparsification algorithm, which leads to optimal values of the sparsification parameter p . Thus, we can justify speedups rigorously rather than the constant speedups of [34].
- A practitioner’s guide on how to run the algorithm in detail. Even if the optimal values of p depend on unknown quantities, including the number of triangles we wish to estimate, the algorithm is of high practical value. Few executions until concentration is deduced, still result in huge speedups.
- Experimentation on large networks, with several millions of nodes and edges.

Finally, both cases presented in Section 5 require a sophisticated sampling procedure (e.g., [31]), rather than a simple one and these are topics of future research.
